On the cause of enhanced landward motion of the overriding plate after a major subduction earthquake

Mario D’Acquisto, Matthew Herman, and Rob Govers

During and after a large megathrust earthquake, the overriding plate above the rupture zone moves oceanward. Enigmatically, the post-seismic motion of the overriding plate after several recent large earthquakes along strike from the rupture zone was faster in a landward direction than before the event. Previous studies interpreted these changes as the result of increased mechanical coupling along the megathrust interface or transient slab acceleration. However, before invoking additional mechanisms, we need to account for in-plane bending of the overriding plate which is an inherent feature of megathrust earthquakes. The aim of our study is to quantify the contribution of in-plane bending of the overriding plate and determine whether additional mechanisms are needed to understand the observations.

We use velocity-driven 3D mechanical finite element models, in which large megathrust earthquakes are taken to occur periodically on the finite plate interface. The model geometry is similar to most present-day subduction zones, but does not exactly match any specific subduction zone.

The results show increased co-seismic and post-seismic landward motion at (trench-parallel) distances greater than 450 km from the edge of the rupture zone. Post-seismic velocities are controlled by both viscous relaxation in the mantle wedge and deep afterslip on the shear zone downdip of the brittle megathrust interface. Landward displacement due to postseismic relaxation largely accumulates at exponentially decaying rates until ~6 Maxwell relaxation times after the earthquake. The spatial distribution of the landward displacements is broadly consistent with observations related to both the 2010 Maule and the 2011 Tohoku-oki earthquakes. The magnitude of the velocity changes is similar to that of published secular velocity changes associated with the Maule event.

Further model experiments show that patterns of landward motion due to afterslip and to viscous relaxation are insensitive to the locking pattern of the megathrust. The locking distribution does affect the magnitudes of the displacements and velocities. The results show that the increased landward displacement due to postseismic deformation scales directly proportionally to seismic moment.

We conclude that the landward motion results from in-plane horizontal bending of the overriding plate and mantle. This bending is an elastic response to oceanward tractions near the base of the plate around the ruptured asperity, causing extension locally and compression further away along-trench. This elastic in-plane bending consistently contributes to earthquake-associated changes in surface velocities for the biggest megathrust earthquakes, producing landward motion along strike from the rupture zone. Additional mechanisms (e.g., increased mechanical locking or slab acceleration) are not needed to explain the observations.
